Estimating and Interpreting Effect Sizes: A Note for 432 Class 12

Thomas E. Love 2019-03-07

A Sample Data Set

Consider the small.csv data available on our site, which is modeled on the public Framingham data set available from BIOLINCC¹. From the BIOLINCC documentation:

The Framingham Heart Study is a long term prospective study of the etiology of cardiovascular disease among a population of free living subjects in the community of Framingham, Massachusetts. The Framingham Heart Study was a landmark study in epidemiology in that it was the first prospective study of cardiovascular disease and identified the concept of risk factors and their joint effects.

¹ The Framingham data from this source are not appropriate for publication or project use because they have been anonymized by permuting the results of individual subjects.

Available Variables

```
smalldat <- read_csv("small.csv")
Parsed with column specification:
cols(
   subject = col_double(),
   smoker = col_double(),
   totchol = col_double(),
   age = col_double(),
   sex = col_character(),
   educ = col_character())</pre>
```

The smalldat data contains 150 observations on the following variables²:

Variable	Description
subject	Subject identification code
smoker	1 = current smoker, o = not current smoker
totchol	total cholesterol, in mg/dl
age	age in years
sex	subject's sex (M or F)
educ	subject's educational attainment (4 levels)

² The *educ* levels are: 1_Low, 2_Middle, 3_High and 4_VHigh, which stands for Very High

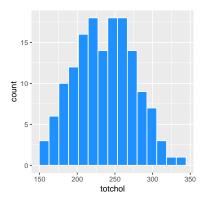

Figure 1: Histogram of totchol values

Effect Interpretation in A Linear Regression Model

m1 <- lm(totchol ~ age + sex + factor(educ), data = smalldat)</pre>

kable(tidy(m1, conf.int = TRUE), digits = 3)

term	estimate	std.error	statistic	p.value	conf.low	conf.high
(Intercept)	171.197	20.201	8.475	0.000	131.268	211.126
age	1.202	0.367	3.270	0.001	0.475	1.928
sexM	3.612	6.441	0.561	0.576	- 9.119	16.343
factor(educ)2_Middle	11.044	7.702	1.434	0.154	-4.18 0	26.268
factor(educ)3_High	-2.459	9.390	-0.262	0.794	-21.019	16.101
factor(educ)4_VHigh	10.927	9.780	1.117	0.266	-8.405	30.258

1. What is the effect of age on totchol in Model m1?

term	estimate	std.error	statistic	p.value	conf.low	conf.high
age	1.202	0.367	3.27	0.001	0.475	1.928

The coefficient of the *age* effect on *totchol* is 1.202. Suppose we have two subjects, Doris and Emily, who are the same sex and have the same level of education, but Doris is one year older than Emily. Our model predicts that Doris' total cholesterol will be 1.202 mg/dl higher than Emily's.

The 95% confidence interval for this estimated age coefficient is (0.475, 1.928), which does not include zero, so we can conclude that there is a statistically significant effect (at the 5% significance level) of age on totchol. Holding everything else constant, older age is associated with significantly higher totchol in this model.

2. What is the effect of sex on totchol in Model m1?

term	estimate	std.error	statistic	p.value	conf.low	conf.high
sexM	3.612	6.441	0.561	0.576	-9.119	16.343

The model is parametrized to incorporate the *sex* information with an indicator (and factor) variable called *sexM* which is interpreted as taking the value 1 when sex = M, and 0 otherwise. The coefficient of the sexM effect on totchol is 3.612. Suppose we have two subjects, David and Emily, who are the same age, have the same level of education, but David is male and Emily is female. Our model predicts that David's total cholesterol will be 3.612 mg/dl higher than Emily's.

The 95% confidence interval for this estimated sexM coefficient is (-9.119, 16.343), which includes zero, so we cannot conclude that there is a statistically significant effect (at the 5% significance level) of sex on totchol.

3. What is the effect of educ on totchol in Model m1?

The *educ* variable splits the subjects into four categories. In this model the "1_Low" category is used as the baseline, and we have estimates for "2_Middle" (as compared to "1_Low"), for "3_High" (as compared to "1_Low") and for "4_VHigh" (as compared to "1 Low".)

term	estimate	std.error	statistic	p.value	conf.low	conf.high
factor(educ)2_Middle	11.044	7.702	1.434	0.154	-4.180	26.268
factor(educ)3_High	-2.459	9.390	-0.262	0.794	-21.019	16.101
factor(educ)4_VHigh	10.927	9.780	1.117	0.266	-8.405	30.258

The coefficient of the educ effect comparing the "2_Middle" group to the baseline "1_Low" group on totchol is 11.044.

Note that none of the educ levels show significant differences from the baseline group, based on their 95% confidence intervals each containing zero.

- Suppose we have two subjects, Lola and Mina, who are the same age, and the same sex, but Lola is in the "1_Low" education group and Mina is in the "2_Middle" education group.
- Our model predicts that Mina's total cholesterol will be 11.044 mg/dl higher than Lola's.

The coefficient of the educ effect comparing the "3_High" group to the baseline "1_Low" group on totchol is -2.459.

- Suppose we have two subjects, Lola and Heidi, who are the same age, and the same sex, but Lola is in the "1_Low" education group and Heidi is in the "3_High" education group.
- Our model predicts that Heidi's total cholesterol will be 2.459 mg/dl lower than Lola's.

Finally, the coefficient of the *educ* effect comparing the "4_VHigh" group to the baseline "1_Low" group on totchol is 10.927.

- Suppose we have two subjects, Lola and Vera, who are the same age, and the same sex, but Lola is in the "1_Low" education group and Vera is in the "4_VHigh" education group.
- Our model predicts that Vera's total cholesterol will be 10.927 mg/dl higher than Lola's.

What if we include a Spline or an Interaction?

Suppose we fit a new model to predict totchol using a five-knot spline in age and the interaction of sex and educational attainment. How does that change our interpretation of the effect sizes?

It should be easy to see that none of the coefficients reach the level of statistical significance here, since zero is contained in each of the 95% confidence intervals provided in the table above summarizing model m2.

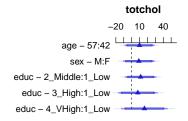

```
d <- datadist(smalldat)</pre>
options(datadist = "d")
m2 <- ols(totchol ~ rcs(age, 5) + sex * catg(educ),</pre>
    data = smalldat, x = TRUE, y = TRUE)
kable(summary(m2), digits = 2)
```

	Low	High	Diff.	Effect	S.E.	Lower 0.95	Upper 0.95	Туре
age	42	57	15	9.99	9.40	-8.59	28.57	1
sex - M:F	1	2	NA	9.11	9.87	-10.41	28.64	1
educ - 2_Middle:1_Low	1	2	NA	11.36	9.81	-8.04	30.76	1
educ - 3_High:1_Low	1	3	NA	7.80	12.41	-16.73	32.34	1
educ - 4_VHigh:1_Low	1	4	NA	16.17	14.63	-12.75	45.10	1

The kable approach I used in these notes hides the adjusted values specified at the bottom of the summary table for this ols model, but they are Adjusted to: sex=F educ=1_Low.

Now, how do we interpret these model m2 results?

- The age interpretation is that if we have two subjects, Al and Bob, who are the same sex and have the same education level, but Al is age 42 and Bob is age 57, then model m2 projects that Bob's totchol will be 9.993 mg/dl higher than will Al's.
- Because of the interaction between sex and educ in our model m2, we must select an educ level in order to cleanly interpret the effect of sex on totchol. The sex - M:F interpretation compares M(ale) to

Adjusted to:sex=F educ=1_Low Figure 2: Summary plot of model m2

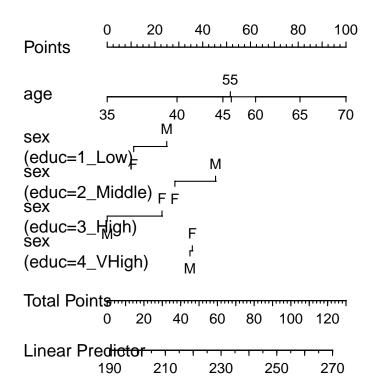

F(emale) sex while requiring³ that educ = 1_Low. The result is that if we have two subjects, Carl and Diane, who are the same age and each is in the low education group, but Carl is Male and Diane is Female, then model m2 predicts that Carl's totchol will be 9.115 mg/dl higher than will Diane's.

Because of the interaction between *sex* and *educ* in our model m2, we must select a sex in order to cleanly interpret the effect of educ on totchol. The educ - 2_Middle:1_Low term, for instance, compares "2_Middle" education to "1_Low" education while requiring that sex is Female⁴. The result is that if we have two subjects, Lola and Mina, who are the same age and each is Female, but Lola is in the "1_Low" education group and Mina is in the "2_Middle" education group, then model m2 predicts that Mina's totchol will be 11.363 mg/dl higher than will Lola's.

Here is a nomogram of model m2.

³ We know this because of the Adjusted to: sex = F, educ=1_Low note at the bottom of the summary output for the ols model.

⁴ Again, we know this because of the Adjusted to: sex = F, educ=1_Low note.

Effect Estimates in A Logistic Regression fit with glm

In a binary **logistic** model, where we predict the log odds of smoking (smoker = 1), we will exponentiate so as to interpret the odds ratio estimates associated with each coefficient.

```
m3 <- glm(smoker ~ age + sex + factor(educ), data = smalldat,
    family = binomial)
kable(tidy(m3, exponentiate = TRUE, conf.int = TRUE),
    digits = 3)
```

term	estimate	std.error	statistic	p.value	conf.low	conf.high
(Intercept)	19.054	1.152	2.557	0.011	2.082	195.209
age	0.943	0.021	-2.782	0.005	0.903	0.982
sexM	1.795	0.356	1.643	0.100	0.897	3.637
factor(educ)2_Middle	0.690	0.428	-0.866	0.386	0.295	1.589
factor(educ)3_High	0.725	0.519	-0.619	0.536	0.258	2.005
factor(educ)4_VHigh	0.339	0.571	-1.895	0.058	0.105	1.008

1. What is the effect of age on the odds of being a smoker in Model m3?

term	estimate	std.error	statistic	p.value	conf.low	conf.high
age	0.943	0.021	-2.782	0.005	0.903	0.982

The estimated odds ratio for the age effect on smoker is 0.943. Suppose we have two subjects, Doris and Emily, who are the same sex and have the same level of education, but Doris is one year older than Emily. Our model predicts that Doris' odds of smoking will be 0.943 times as high as Emily's.

The 95% confidence interval for this estimated odds ratio for the age effect on being a smoker is (0.903, 0.982). This confidence interval for the odds ratio does not include one, so we can conclude that there is a statistically significant effect (at the 5% significance level) of age on smoker. Holding everything else constant, older age is associated with significantly lower odds of being a *smoker* in this model.

2. What is the effect of sex on the odds of being a smoker in Model m3?

term	estimate	std.error	statistic	p.value	conf.low	conf.high
sexM	1.795	0.356	1.643	0.1	0.897	3.637

The model is parametrized to incorporate the sex information with an indicator (and factor) variable called *sexM* which is interpreted as taking the value 1 when sex = M, and 0 otherwise. The estimated odds ratio describing the sexM effect on being a smoker is 1.795. Suppose we have two subjects, David and Emily, who are the same age, have the same level of education, but David is male and Emily is female. Our model predicts that David's odds of being a smoker are 1.795 times the odds that Emily is a *smoker*.

The 95% confidence interval for the odds ratio estimate of the effect of sexM on being a smoker is (0.897, 3.637). Since this confidence interval for the odds ratio includes one, we cannot conclude that there is a statistically significant effect (at the 5% significance level) of sex on the odds of being a smoker.

3. What is the effect of educ on the odds of being a smoker in Model m3?

Again, the *educ* variable splits the subjects into four categories. In this model the "1_Low" category is used as the baseline, and we have estimates for "2_Middle" (as compared to "1_Low"), for "3_High" (as compared to "1_Low") and for "4_VHigh" (as compared to "1_Low".)

term	estimate	std.error	statistic	p.value	conf.low	conf.high
factor(educ)2_Middle	0.690	0.428	-0.866	0.386	0.295	1.589
factor(educ)3_High	0.725	0.519	-0.619	0.536	0.258	2.005
factor(educ)4_VHigh	0.339	0.571	-1.895	0.058	0.105	1.008

The estimated odds ratio describing the effect of educ being "2_Middle" instead of the baseline "1_Low" on the odds of being a smoker is 0.69.

Note that none of the *educ* levels show significant differences from the baseline group, based on their 95% confidence intervals all including 1, although the comparison of 4_VHigh to 1_Low is close to significant.

- Suppose we have two subjects, Lola and Mina, who are the same age, and the same sex, but Lola is in the "1_Low" education group and Mina is in the "2_Middle" education group.
- Our model predicts that Mina's odds of being a smoker will be 0.69 times the odds of Lola being a smoker.

The estimated odds ratio comparing the educ = "3_High" group to the baseline *educ* = "1_Low" group on *smoker* is 0.725.

- Suppose we have two subjects, Lola and Heidi, who are the same age, and the same sex, but Lola is in the "1_Low" education group and Heidi is in the "3_High" education group.
- Our model predicts that Heidi's odds of being a smoker will be 0.725 times the odds of Lola being a smoker.

Finally, The estimated odds ratio comparing the *educ* = "4_VHigh" group to the baseline *educ* = "1_Low" group on *smoker* is 0.339.

- Suppose we have two subjects, Lola and Vera, who are the same age, and the same sex, but Lola is in the "1_Low" education group and Vera is in the "4_VHigh" education group.
- Our model predicts that Vera's odds of being a *smoker* will be 0.339 times the odds of Lola being a smoker.

Estimates in The Same Logistic Regression fit with 1rm

When we fit the same model as m3 using lrm, we get identical results as we get from the glm fit for the categorical predictors, but there's a change in how the odds ratio for the quantitative predictor (age) is presented.

```
d <- datadist(smalldat)</pre>
options(datadist = "d")
m3.lrm <- lrm(smoker ~ age + sex + educ, data = smalldat,
    x = TRUE, y = TRUE
kable(summary(m3.lrm), digits = 3)
```

	Low	High	Diff.	Effect	S.E.	Lower 0.95	Upper 0.95	Туре
age	42	57	15	-0.885	0.318	-1.508	-0.261	1
Odds Ratio	42	57	15	0.413	NA	0.221	0.770	2
sex - M:F	1	2	NA	0.585	0.356	-0.113	1.283	1
Odds Ratio	1	2	NA	1.795	NA	0.893	3.607	2
educ - 2_Middle:1_Low	1	2	NA	-0.370	0.428	-1.209	0.468	1
Odds Ratio	1	2	NA	0.690	NA	0.299	1.596	2
educ - 3_High:1_Low	1	3	NA	-0.321	0.519	-1.338	0.696	1
Odds Ratio	1	3	NA	0.725	NA	0.262	2.005	2
educ - 4_VHigh:1_Low	1	4	NA	-1.082	0.571	-2.201	0.037	1
Odds Ratio	1	4	NA	0.339	NA	0.111	1.038	2

Note that the odds ratio effect sizes and confidence intervals are identical to what we saw in the glm fit for the sex and educ variables here, but the age result is presented differently.

- The age interpretation is that if we have two subjects, Al and Bob, who are the same sex and have the same education level, but Al is age 42 and Bob is age 57, then model m3 projects that Bob's odds of being a smoker will be 0.413 times higher than will Al's odds of being a smoker.
- Note that the effect of age on the odds of being a smoker is still statistically significant at the 5% level, because the confidence interval for the odds ratio does not contain 1. Since it is entirely less than 1, we can conclude that in this model, after adjustment for sex and educ, increasing age is associated with decreasing odds of smoking.

Estimates in A New Logistic Regression fit with 1rm

Now, suppose we fit a new model to predict the log odds of being a smoker using a five-knot spline in age and the interaction of sex and educational attainment. How does that change our interpretation of the effect sizes?

It should be easy to see that one is contained in each of the 95% confidence intervals summarizing model m4 except for the one for the main effect of sex, but we should make significance decisions for this model using anova, since an interaction is involved.

```
d <- datadist(smalldat)</pre>
options(datadist = "d")
m4 <- lrm(smoker ~ rcs(age, 5) + sex * catg(educ),
    data = smalldat, x = TRUE, y = TRUE)
```

kable(summary(m4), digits = 3)

```

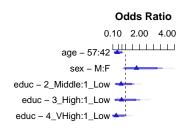

Figure 3: Summary plot of model m3.lrm

	Low	High	Diff.	Effect	S.E.	Lower 0.95	Upper 0.95	Туре
Odds Ratio	1	3	NA	1.019	NA	0.259	4.011	2
educ - 4_VHigh:1_Low	1	4	NA	-1.541	1.159	-3.813	0.731	1
Odds Ratio	1	4	NA	0.214	NA	0.022	2.078	2

Again, the kable approach I used in these notes hides the adjusted values specified at the bottom of the summary table for this 1rm model (model m4), but they are Adjusted to: sex=F educ=1_Low.

Now, how do we interpret these model m4 results?

- The age interpretation is that if we have two subjects, Al and Bob, who are the same sex and have the same education level, but Al is age 42 and Bob is age 57, then model m4 projects that Bob's odds of being a smoker will be 0.442 times higher than Al's odds of being a smoker.
- Because of the interaction between sex and educ in our model m4, we must select an *educ* level in order to cleanly interpret the effect of sex on smoker. The sex - M:F interpretation compares M(ale) to F(emale) sex while requiring⁵ that educ = 1_Low. The result is that if we have two subjects, Carl and Diane, who are the same age and each is in the low education group, but Carl is Male and Diane is Female, then model m4 predicts that Carl's odds of being a smoker will be 4.422 times higher than will Diane's.
- Because of the interaction between sex and educ in our model m4, we must select a sex in order to cleanly interpret the effect of educ on totchol. The educ - 2_Middle:1_Low term, for instance, compares "2_Middle" education to "1_Low" education while requiring that sex is Female⁶. The result is that if we have two subjects, Lola and Mina, who are the same age and each is Female, but Lola is in the "1_Low" education group and Mina is in the "2_Middle" education group, then model m4 predicts that Mina's odds of being a smoker will be 1.951 times higher than will Lola's.

Odds Ratio

Adjusted to:sex=F educ=1_Low Figure 4: Summary plot of model m4

⁵ We know this because of the Adjusted to: sex = F, educ=1_Low note at the bottom of the summary output.

⁶ Adjusted to: sex = F, educ=1_Low tells us this.

Here is a nomogram of model m4.
